1.0 EXECUTIVE SUMMARY

The Sediment Management Standards (WAC 173-204) specify that the first step in the cleanup process is to identify clusters of contiguous stations that exceed the listed sediment quality standards (SQS). The rule does not provide detailed instructions for identifying station clusters, and several alternative approaches are discussed and evaluated in this technical memorandum.

Contiguous stations are defined as those stations that share an edge of a Thiessen polygon, where the Thiessen polygon about each station encloses all points closer to that station than to any other.

Identification of station clusters is expected to be accomplished by applying professional judgment to the result of an objective numerical assessment. The identities of the chemicals that exceed the SQS, and the factors by which they exceed, is the only information that is sure to be available for all stations and upon which a numerical assessment can be based.

A simple objective technique for defining station clusters is to examine the similarity of chemicals and exceedance factors at adjacent stations. Four similarity indices and two similarity tests were evaluated by applying them to data from Elliott Bay. Clusters can be defined based on similarity indices by grouping into a single cluster all contiguous stations that have a similarity that exceeds some critical value. Selection of an appropriate index and critical value requires professional judgment.

Two important criteria for evaluating the similarity indices are their coverage (i.e., what proportion of stations exceeding the SQS are included in a cluster) and their definition (i.e., how well does one value of a similarity index discriminate different clusters compared to another). Because for most sites, coverage will probably not be complete except possibly at very low critical values, the groups of stations identified on the basis of a critical value of a similarity index might be best referred to as cluster fragments. Professional judgment may dictate that fragments be combined to form clusters, and that stations that exceed the SQS and adjoin one or more fragments, but are not included because of low similarity, also be added to a fragment to make a cluster.

Two of the similarity indices evaluated (identified as SIMI2 and SIMI4) have the greatest coverage of the alternatives evaluated. At equal critical values, SIMI2 has slightly greater coverage in Elliott Bay and SIMI4 has greater definition. SIMI2 has considerably better coverage in the area of West Point and the Four-Mile Rock disposal area, and is recommended for application to other sites.

The use of similarity indices as an objective technical basis for cluster identification seems to be a useful approach, as the results (for some indices) can provide good coverage and definition, and conform to the expectations of best professional judgment. Further work may focus on the refinement of the similarity indices and alternative methods for displaying and interpreting the results.

2.0 INTRODUCTION

Section 173-204-510 of the Sediment Management Standards rule specifies that station clusters shall be identified prior to cluster screening and site identification. The rule does not describe any specific method for identifying station clusters. Alternative techniques for identifying clusters include: 1) best professional judgment, 2) a deterministic (i.e., consistently computable) calculation, or 3) a combination of the two methods. This document describes the search for a deterministic method of defining station clusters that may be used either alone or in combination with professional judgment. This document does not describe all of the elements of professional judgment that may be applied in addition to, or instead of, the deterministic methods that are evaluated.

3.0 DESCRIPTION OF THE APPROACH

The technical approach that was followed to evaluate methods of identifying station clusters entailed the following four steps:

1. Define contiguity
2. Determine a technical basis for grouping contiguous (adjacent) stations into a cluster of concern
3. Propose alternative methods that are consistent with the technical basis
4. Test the alternatives.

Contiguity alone was presumed to be insufficient to determine station clusters because of the possibility that a chain or network of contiguous contaminated stations might extend over large portions of the sound. This presumption was confirmed after contiguity was defined and the definition applied to the area selected to test station clustering alternatives.

3.1 DEFINITION OF CONTIGUITY

Stations with sediment chemistry data are located irregularly throughout Puget Sound, depending on the various purposes of the studies that established them. Within a single general area, such as an urban bay, stations may be as close as a few tens of feet or as far apart as several thousands of feet. The distances between stations are even larger—many miles—in the main basin of the sound.

One approach to defining contiguity would be to establish a criterion for linear separation. For example, two stations might be defined to be contiguous if they are less than 250 feet apart. The large variance in inter-station distances renders this approach infeasible as a primary means of establishing contiguity. A small distance criterion would isolate many stations, leaving them with no neighbors. A large distance criterion would not allow use of all the data in intensively sampled areas, where clusters of a size less than the distance criterion might be otherwise discriminated. A modification of this approach would be to adjust the distance criterion according to some set of rules, perhaps dependent upon the actual spacing between stations in an area or on the distance from shore.

This approach was not adopted because of the likely complexity, and possibly controversial nature, of any such rules. However, a distance criterion might be used to modify the approach selected, as described below.

Another approach to defining contiguity would be to establish a criterion for the number of neighbors that are defined to be contiguous to each station. Using this scheme, the four or six (or some other number) nearest neighbors to a given station would be considered contiguous. The absence of a technical basis for selecting any single nearest-neighbor criterion led to the rejection of this approach.

For this study contiguity was evaluated by constructing about each station a polygon that enclosed all points closer to that station than to any other (a Thiessen polygon). Two stations were judged to be contiguous if the Thiessen polygons of each shared an edge. If the Thiessen polygons of two stations shared only a vertex, they were not considered contiguous. This approach should be combined with a distance cutoff criterion so that no two stations separated by a distance greater than this criterion could be considered contiguous under any circumstances. Such a distance cutoff criterion was not used in this study; the study area boundary (described below) established the limit to the number of stations that were to be considered.

The Thiessen polygons for a set of stations can be constructed graphically using the following procedure:

1. Construct straight lines (radii) from each station to every other nearby station that can be reached without crossing any other lines

2. Construct the perpendicular bisectors of each of the radii created in step 1 (edges)

3. Remove all portions of each edge except the segment that lies between the intersections with the edges associated with the radii immediately to the left and right. Edges that intersect the neighboring edges distal to the intersection of the neighboring edges with each other or that are completely outside the smallest polygon around the station should be removed entirely.

Stations at the border of an area will not be completely enclosed by polygons. To complete the polygons around the border stations, a set of imaginary stations may be constructed outside the border. It is recommended that the distance from the imaginary stations to the border be equal to the distance from the border stations to the closest interior station. Closure of the border polygons is not strictly necessary to identify the stations contiguous to the border stations, but may be important to calculate other attributes of the stations, such as the area associated with each station.

3.2 THE TECHNICAL BASIS FOR IDENTIFYING STATION CLUSTERS OF CONCERN

Development of a technical basis for clustering stations is predicated on the assumption that the stations in a cluster should have something in common other than simple contiguity. Because the long-term effectiveness of sediment cleanup depends upon source control, the source of sediment contamination is the most reasonable basis for commonality. Ideally, stations contaminated by the same sources should not be clustered with stations contaminated by different sources. In practice, identification of a direct link from each station to a source (or sources) is likely to be impossible to achieve, and would require more information than is available in the database of sediment chemistry and biology measurements.

Stations that are affected by the same source(s) of contaminants are expected to be characterized by similar suites of contaminants present at concentrations above the sediment quality standards (SQS) listed in the rule. Although the amount by which each contaminant exceeds its SQS (the exceedance factor) is likely to vary with distance from the source, the suite of chemicals, and their relative exceedance factors, are expected to be similar at all stations affected by the same source(s). The list of chemicals and the relative exceedance factors is expected to serve as a fingerprint to identify related stations. Contiguous stations with similar chemical fingerprints should be clustered together, and apart from stations with different fingerprints.

Two different approaches to using this fingerprint information could be taken:

1. Generate a numerical representation of the fingerprint for each station and compare these numbers at each pair of adjacent stations
2. Directly compare the fingerprint information at each pair of adjacent stations.

Both of these approaches require a comparison of adjacent stations. The first approach requires comparison of two single numbers, and the second approach requires a comparison of two lists of chemical names and exceedance factors. Both comparisons must be measured against some established criteria. Because stations in a cluster are not expected to be identical, a comparison must be made with respect to a criterion that dictates how similar two stations must be if they are to be included in the same cluster.

Although the first approach involves a simpler comparison, it requires development of an algorithm that will generate a unique value for every possible combination of chemicals and exceedance factors. Diversity indices that are commonly applied to biological communities were evaluated for their applicability to stations with contaminated sediments. Species diversity indices are based on

a data set that contains a number of species, each of that has an integer number of members. This situation is superficially similar to a station that has a number of chemicals exceeding the SQS, each of which has a (non-integer) exceedance factor. Most species diversity indices depend on the fact that the number representing each variable (species abundance, in the case of biological data) is an integer (e.g., by reliance on factorials or properties of the binomial distribution). These indices cannot be applied to stations where the number representing each chemical is a non-integer, such as the concentration or exceedance factor. Other species diversity indices lack clear biological relevance; their analogues, if applied to a contaminated station, would also be difficult to justify.

The second approach requires adoption or development of an algorithm that will generate a similarity value for each pair of adjacent stations. This similarity value directly represents the results of a comparison between the two stations. Two stations that have exactly the same suite of chemicals might be assigned a similarity value of 1.0; two other stations might also have a similarity value of 1.0 based on the common occurrence of a different suite of chemicals. Similarity values need only be evaluated locally, rather than compared across the entire site, as a diversity index or analogous value would. A similarity index therefore need not produce a unique value for each possible combination of chemicals and exceedance factors. This less rigorous requirement of the second approach resulted in its adoption for this study.

The following variables, effects, or factors might be included (either individually or in combination) in a similarity index:

- The number of chemicals (exceeding the SQS) common to the two stations
- The number of chemicals (exceeding the SQS) not common to the two stations
- The rank ordering of exceedance factors at the stations, individually or in combination
- The actual magnitude of the exceedance factors
- The degree of adjacency of the two stations (e.g., the length of the common edge of the Thiessen polygons about the stations).

Concentration values, rather than exceedance factors, could be used as a basis for the calculation of similarity indices. This approach would allow a comparison of fingerprints even when most of the chemicals at one or both stations do not exceed the SQS.

3.3 ALTERNATIVE METHODS

Six alternative methods were chosen for testing. Four methods produce a numerical similarity index for each pair of adjacent stations, and two methods produce a yes-or-no indication of similarity based on statistical tests. All six methods are described in Section 4.

3.4 TESTING OF THE ALTERNATIVES

Elliott Bay was selected as a site for testing the alternative approaches. Elliott Bay is a complex site, with potentially many sources, station separations ranging from tens of feet to over 11,000 feet, and contiguous contaminated stations that extend throughout much of the bay. Elliott Bay is expected to be representative of the most complex conditions to which the station clustering method will be applied.

The major sources known to exist in Elliott Bay are:

- Industrial activities on Harbor Island
- The Denny Way combined sewer overflow (CSO)
- The West Point sewage treatment plant outfall
- The Four-Mile Rock dredged material disposal site.

In addition, numerous small sources are presumed to exist to the west of Harbor Island and along the Seattle waterfront.

Previous reviews conducted for Ecology of the distributions of contaminants in Elliott Bay have revealed fairly distinct regions of contamination that are associated with Harbor Island, the Denny Way CSO, the West Point outfall, and the Four-Mile Rock site. Contaminated sediments are also present in Elliott Bay off the mouth of the Duwamish River and along the Seattle waterfront. Evaluation of the alternative methods was therefore focused on:

- Their ability to clearly delineate a cluster in each of the areas of Harbor Island, the Denny Way CSO, the West Point outfall, and the Four-Mile Rock site
- Their ability to produce distinct clusters on the Seattle waterfront and off the mouth of the Duwamish River.

These two points require that the results of the clustering method be 1) in accord with expectations based on a prior application of professional judgment (where applicable), and 2) supported by subsequent application of professional judgment where no prior application has been performed.

4.0 DESCRIPTION OF THE ALTERNATIVES

Six similarity measures were selected for evaluation. These similarity measures are described in the following sections. To allow concise references to the similarity measures, they have been designated SIMI1, SIMI2, SIMI3, SIMI4, SIMI5, and SIMI6.

Each description of one of the similarity measures in the following sections includes a formula or series of steps for calculating the similarity measure. These formulas express the calculation of the similarity index for two stations, A and B. Other symbols used in these formulas have the following meanings:

N_A = the number of chemicals that exceed the SQS at station A

N_B = the number of chemicals that exceed the SQS at station B

C_{AB} = the number of chemicals that exceed the SQS at both A and B (i.e., are common to both A and B)

T_{AB} = the total number of (unique) chemicals that exceed the SQS at either A or B

F_{Ai} = the exceedance factor for chemical i at station A, where i ranges from 1 to N_A

F_{Bi} = the exceedance factor for chemical i at station B, where i ranges from 1 to N_B.

Additional terms are introduced in the following sections as needed.

Several of the similarity indices employ a measure known as the relative proportional difference (RPD). The RPD of two numbers x and y is calculated as:

$$\frac{|x-y|}{\left(\frac{x+y}{2}\right)}$$

That is, the RPD is the difference between the two values divided by the mean of the two values. (This value is sometimes multiplied by 100 and called a relative percent difference.) The RPD is analogous to the coefficient of variation which can be computed for multiple (normally distributed) observations. An RPD of zero indicates that the two numbers (e.g., x and y) are equal. Larger values of the RPD indicate greater differences between the two numbers. Although an RPD cannot be greater than 2.0, an RPD of 1.0, means that the difference between the two numbers is twice as great as the smaller number. An RPD of 1.0 is treated as a practical upper bound for the similarity indices presented here. The expression ***1.0*** **- RPD** is used to express the similarity [or relative proportional similarity (RPS)] between two individual numbers.

These similarity measures each include one or more of the effects listed in Section 3.2, with the exception of the degree of adjacency of the two stations. The degree of adjacency is regarded as a factor that could be used to modify some of the similarity measures below. Because it affects the two stations as a whole, and does not have different effects on individual chemicals at one or the other station, the degree of adjacency could be applied to the similarity indices described below as a single multiplicative factor. The similarity measures to which this factor might be applied all have a fixed upper bound (1.0) that represents perfect similarity. If degree of adjacency were represented simply by the length of the common edge of the Thiessen polygon (e.g., in meters), the fixed upper bound of these similarity measures would be lost. Scaling of the degree-of-adjacency factor would preserve a fixed upper bound to these similarity measures. Selection of an appropriate scaling factor is difficult, given the wide variety of station densities, for the same reasons discussed in Section 3.1 with regard to contiguity. During the evaluation of these similarity measures, no modifying factor based on the degree of adjacency was applied.

4.1 THE FIRST SIMILARITY INDEX (SIMI1)

This is the simplest of the six similarity indices; it consists of the ratio of the chemicals common to the two stations to the total number of chemicals at both stations, or:

$$SIMI1 = \frac{C_{AB}}{T_{AB}}$$

This similarity index takes into account only the numbers of chemicals in common and the total number of unique chemicals at the two stations. SIMI1 does not take into account the rank order or the magnitudes of the exceedance factors at

the two stations. Values of SIMI1 can range from 0 (no similarity) to 1.0 (perfect similarity). A modifying factor based on degree of adjacency could be applied to this similarity measure.

4.2 THE SECOND SIMILARITY INDEX (SIMI2)

In addition to the numbers of chemicals in common and not in common at the two stations, the second similarity index takes the relative ordering of exceedance factors at the two stations into account. It is based on a comparison of the rank at each station of each chemical that exceeds the SQS at each station. The comparisons are made using an RPD, and the results are averaged for all chemicals in common at the two stations.

This similarity index can be expressed by the formula:

$$SIMI2 = \frac{\sum_{i=1}^{C_{AB}} \left(1.0 - \frac{|R_{Ai} - R_{Bi}|}{\left(\frac{R_{Ai} + R_{Bi}}{2} \right)} \right)}{C_{AB}}$$

where

R_{Ai} = the proportional rank of chemical i at station A.

The following procedure is used to calculate this similarity index:

1. Rank the chemicals at each station by their exceedance factors. The chemical at each station with the lowest exceedance factor should have a rank of 1; the chemical with the highest exceedance factor should have a rank equal to the number of chemicals that exceed the SQS at that station.
2. Compute the proportional rank of each chemical at each station by dividing the rank (computed in step 1) by the number of chemicals that exceed the SQS at that station.
3. For every chemical that exceeds the SQS at both stations, compute the RPS of the proportional ranks at the two stations.
4. Sum all of the RPS values.
5. Divide the sum by the number of chemicals that exceed the SQS at both stations.

5.0 EVALUATION OF THE ALTERNATIVES

After the six similarity measures were formulated, they were all applied to Elliott Bay stations using data from the SEDQUAL database. This data set included measurements at approximately 500 stations from 21 different surveys. Data completeness has a potentially large impact on all of the similarity measures to be evaluated. For example, if chemicals that exceed the SQS at one station were not measured at an adjacent station, the similarity index of the two stations will be based on incomplete data (if it can be calculated at all). For the purpose of this evaluation, no attempt was made to define data completeness or to eliminate stations with incomplete data sets.

5.1 COMPUTATION

Values for all six similarity indices for all adjacent stations in Elliott Bay were calculated by a computer program written for that purpose. This calculation requires two types of data:

- A list of the chemicals that exceed the SQS at each station, including the exceedance factor for each chemical
- A list of all adjacent pairs of stations in Elliott Bay.

Chemical exceedance factors were produced by performing a comparison of the SQS criteria to all stations in Elliott Bay using SEDQUAL's built-in routines, saving the results as a text file in the form of SEDQUAL's standard output table for sediment quality value comparisons, and transforming this table to a form that would be more easily read by custom software. The table of exceedance factors, in the form that it was used for computation of similarity indices, is listed in Appendix A. Included in that appendix is a description of the technique used to transform the SEDQUAL output table to the form shown.

A list of all adjacent station pairs in Elliott Bay was produced by generating Thiessen polygons for all stations and a triangulated irregular network (TIN) for all stations using ARC/INFO®. The TIN is the inverse of the set of Thiessen polygons—in the TIN, each station is connected to each of its nearest neighbors by a line. Using the Thiessen polygons as a reference, spurious lines (such as those that crossed land areas) were removed from the TIN. ARC/INFO® was then used to produce a list of all pairs of stations connected by a line in the TIN. This list of station pairs is presented in Appendix B, in exactly the form used for the calculation of similarity indices.

The computer program used to calculate similarity among stations is listed in Appendix C. This program was run once using the data shown in Appendices A and B as input.

5.2 EVALUATION

The calculated similarity values for all pairs of adjacent stations in Elliott Bay that exceed the SQS criteria are shown in Table 1. Two aspects of the results can be noted from examination of the table:

- A value for SIMI5 was not computable in most cases because too few chemicals (fewer than six) exceeded the SQS criteria at adjacent stations to allow statistically valid interpretation
- Negative values occur for SIMI2, SIMI3, and SIMI4 (most often for SIMI4) as a consequence of RPDs greater than 1.0 (that is, the difference between the two values is greater than their mean).

Two conclusions can be drawn from these observations:

- SIMI5 should not be further considered for use in defining clusters, as it is rarely applicable. This limitation may be reduced if concentrations, including those below the SQS, are used instead of exceedance factors.
- RPD values should be subtracted from 2.0 rather than 1.0 and then re-scaled (e.g., by division by 2.0) to fall within the range of 0.0 to 1.0.

Station pairs with negative similarity indices have some chemical(s) in common and are therefore more similar than station pairs with a similarity index of zero, which have no chemical(s) in common. This "hole" in the distribution of similarity values can be easily remedied by reformulating the expression for relative percent similarity. Such a change would not affect the relative magnitudes of the non-zero similarity values shown in Table 1.

5.2.1 Correlations

Pearson correlation coefficients between all combinations of the first four similarity indices were computed as an indication of the relative impact of the different weights given by the different similarity indices to the number of chemicals in common, the number of chemicals not in common, and the magnitudes of exceedance factors. SIMI1, SIMI2, and SIMI3 were all significantly correlated with one another ($p < 0.001$); SIMI1 and SIMI3 were most highly correlated, with a coefficient of 0.879. SIMI4 was not significantly correlated with any of the other indices.

[a] NC: not computable; SIM: not significantly different; DIS: significantly different

SIMI2 and SIMI3 measure the pattern of exceedances in very similar ways, so a highly significant correlation between them is not surprising. SIMI1 is highest for pairs of stations that have a large proportion of the total number of chemicals in common; the significant correlation of SIMI1 with SIMI2 and SIMI3 indicates that this relationship holds for the latter two similarity indices also. In particular, the use of proportional ranks in SIMI2 and SIMI3 seems to weight chemicals that are not common to the two stations equivalently to SIMI1.

SIMI4 measures the pattern of exceedances in a way very similar to SIMI2 and SIMI3, but with more weight given to the magnitudes of the exceedance factors (rather than just their ranks) and no weight given to chemicals that are not common to the two stations. The lack of a significant correlation between SIMI4 and SIMI2, SIMI3, or SIMI1 indicates that either or both of the following effects are operative:

- The variability of concentrations between similar stations is much greater than the variability of the ranks of concentrations. That is, although the chemicals at several stations may be ranked similarly by concentration, the chemical concentrations at the stations may differ greatly in magnitude.
- The proportion of chemicals that are not in common at the two stations strongly influences SIMI1, SIMI2, and SIMI3.

A highly significant correlation between SIMI1 and SIMI3 is not expected based strictly on the formulation of the similarity indices (as it is for SIMI2 and SIMI3). This observation may mean that there are relatively few discrete suites of chemicals that exceed the SQS in Elliott Bay, and that each suite has a characteristic SIMI1 ratio. If this interpretation is correct, it may be that the number of chemicals in common at two stations (C_{AB}) is also characteristic of a particular suite of chemicals. Also, such a relationship may become weaker as it is extended to more areas with more diverse sources and types of contaminants.

Because of the binary nature of the results of the SIMI5 and SIMI6 statistical similarity measures, a Pearson correlation coefficient cannot be calculated. Examination of the results (Table 1), however, shows that there is generally good agreement between these two methods in the cases when SIMI5 can be calculated. When the two methods yield different conclusions, SIMI6 usually indicates a significant difference (dissimilarity) between the two stations where SIMI5 does not. This observation indicates that SIMI6 is more sensitive to differences between stations and provides more resolution in the definition of clusters.

5.2.3 Frequency Distributions

The distributions of values for each of the first four similarity measures are shown in Figures 1–4. The purpose of generating these frequency distributions was to determine if the values showed a bimodal distribution or other indication of two general classes of similarity values (high and low). The rationale for expecting such a distribution is that a high similarity would be found between pairs of stations within a cluster and a low similarity would be found between pairs of stations in which either both stations were outside a cluster or one station was inside a cluster and the other outside.

Only SIMI2 shows a clearly bimodal distribution, with a division between high and low similarity values at 0.6-0.7. Both SIMI1 and SIMI3 show a distinct decrease in the frequency of values above 0.5. No clear inflection point can be seen in the distribution of SIMI4 values.

5.2.4 Cluster Definition

To evaluate the potential of the similarity measures to identify station clusters, maps were prepared showing the distribution of similarity values throughout Elliott Bay. Several maps were prepared for each of SIMI1-SIMI4, identifying all stations that had a similarity index greater than or equal to some critical value with regard to one or more of its neighbors. For example, because the frequency distribution of SIMI2 values shows an inflection point near 0.6, maps were prepared showing stations that had SIMI2 values greater than or equal to 0.4, 0.5, 0.6, and 0.8. In the case of SIMI6, one map was prepared showing stations that had significant *vs* non-significant similarities with one or more neighbors.

To aid the visual identification of clusters, the polygons of adjacent stations that have a similarity index equal to or above the critical value were shaded similarly. Four different types of shadings were used. For example, if station A is judged highly similar to both B and C, they will all be shaded the same (even if B and C are adjacent and not highly similar with each other). If stations D and E are similar to each other and adjacent to A, B, or C, but not similar to A, B, or C, they will be shaded differently than A, B, and C. Examples of these maps are shown in Figures 5 and 6, which illustrate the groups of stations defined by SIMI2 critical values of 0.4 and 0.8, respectively. All stations that exceed the SQS are shown in Figure 7.

When adjacent stations are highly similar to other stations, but not to each other (either directly or indirectly), best professional judgment will be required to decide if these stations should be in the same cluster. For convenience in the

following discussion, and to avoid presumptions about the final form of clusters, each group of similar polygons will be referred to as a cluster fragment (or simply fragment). Best professional judgment may dictate that distinct fragments be combined to form clusters.

Examination of these maps revealed two important aspects of the distributions of fragments:

- *Coverage*—the proportion of all stations that exceed the SQS that are included in a fragment
- *Definition*—the number of distinct fragments.

An ideal critical value of a similarity index would maximize both coverage and definition.

Even at very low critical values, coverage may not be complete. For example, stations that exceed the SQS but are not adjacent to any other stations that exceed the SQS will never be included in any fragment. In general, however, coverage is greater at lower similarity values. Best professional judgment may dictate stations that exceed the SQS but are not included in any fragment be added to one or another fragment to form a cluster.

Fragments that are distinguished (i.e., shaded differently) at high similarity values may not be distinguished at low similarity values because at low similarity values there may be one or more stations that are similar to both fragments, thereby linking them into a single fragment. In contrast, the greater number of stations included (greater coverage) at low critical values may lead to an increase in the number of distinct fragments at low critical values. Definition therefore does not necessarily vary consistently with the critical value.

Coverage of each of the similarity measures at a variety of critical values is illustrated by Table 2, which shows the numbers of stations that have a similarity equal to or greater than selected critical values. A total of 226 stations exceed the SQS in Elliott Bay. Similarity indices SIMI1 and SIMI3 produced low coverage even at low critical values. SIMI2 and SIMI4 produced the greatest coverage and the least decrease in coverage with increasing critical value.

Table 3 shows the definition of SIMI2 and SIMI4 at a variety of critical values. SIMI4 produces consistently better definition.

Both of these similarity indices produce comparable coverage and definition in the areas of Harbor Island, the Denny Way CSO, the Seattle shoreline, and the shoreline to the west of Harbor Island. SIMI4, at a critical value of 0.8, shows slightly greater coverage in the area of the north Seattle shoreline and greater definition in East and West waterways than does SIMI2. Although SIMI4 shows greater definition at a critical value of 0.8 than does SIMI2, with only slightly

TABLE 2. COVERAGE OF SIMILARITY MEASURES AT SELECTED CRITICAL VALUES[a]

	Critical Value					
Index	0.2	0.4	0.5	0.6	0.8	Not sig. different
SIMI1		78		36	19	
SIMI2	130	116	105	91	60	
SIMI3		43		22	15	
SIMI4	182	110	102	88	58	
SIMI6						51

[a] The table shows the number of stations with a relationship to one or more adjacent stations that is at or above the selected critical value.

TABLE 3. NUMBER OF CLUSTER FRAGMENTS DEFINED BY THE INDICATED CRITICAL VALUE

	Critical Value								
Index	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
SIMI2	12	12	14	19	22	21	22	18	16
SIMI4	15	17	22	21	24	23	24	24	20

less coverage, it does not include any stations in the area of West Point and has considerably less coverage in the area of the Four-Mile Rock disposal site (one fragment of three stations for SIMI4 compared to three fragments of seven stations for SIMI2). The greatest difference between SIMI2 and SIMI4 at a level of 0.4 also occurs in the area of West Point. In this case, SIMI2 identifies a single fragment of 16 stations (excluding Magnolia Bluff), and SIMI4 identifies three fragments with a total of 11 stations.

The better correspondence of SIMI2 with known sources and observed distributions of contaminants indicates that it is preferable to SIMI4 as a basis for defining station clusters. Because definition remains high down to critical values of 0.4 for SIMI2 and 0.3 for SIMI4, low values of these similarity indices can be used to identify cluster fragments. Further definition of some fragments can be achieved by examining the fragments produced by a higher critical value.

6.0 CONCLUSIONS AND RECOMMENDATIONS

The results of the evaluation described in preceding sections indicate that similarity measures can be used as a consistent and technically justifiable basis for identifying station clusters. Other available information, such as the presence of known sources, should be incorporated into the cluster identification process via professional judgment. Professional judgment may suggest that cluster fragments identified on the basis of similarity indices be coalesced into clusters and that clusters may include other stations as well.

Although one of the similarity measures considered here, SIMI2, provides good coverage and definition, selection of a single critical value of any single similarity measure may not be the most appropriate means of using this technique. Examination of the fragments defined by a variety of critical levels of different similarity measures is recommended until additional data are collected to define the performance of these similarity measures at a variety of sites. Consideration of similarity measures other than those evaluated in this report may be appropriate.

Further work in this area could be devoted to:

- Evaluation of additional similarity measures.
- Evaluation of the similarity measures at different sites.
- Evaluation of the effect of using the concentrations of all chemicals, not just those exceeding the SQS, to compare the "fingerprints" of adjacent stations.
- Re-formulation of SIMI2, SIMI3, and SIMI4 to eliminate the possibility of negative values.
- Development of criteria for data completeness, so that stations for which a representative suite of chemicals has not been measured will not be included in the analysis.
- Development of additional techniques and computerized tools to assist interpretation of the results of the similarity analysis. One potential technique is to "grow" clusters outward from locations of high similarity, thus achieving both maximum coverage and maximum definition.
- Development of guidelines for the application of best professional judgment, including consideration of specific chemicals, inter-station distances, and other site-specific information.

APPENDIX A

Exceedances of Sediment Management Standards in Elliott Bay

APPENDIX A
Exceedances of Sediment Management Standards in Elliott Bay

This appendix lists the chemical data for Elliott Bay used to evaluate the similarity measures SIMI1–SIMI6. The original source for this data is the SEDQUAL database. SEDQUAL was used to compare the chemical data to the SQS criteria and to produce a formatted output table as a computerized text file. The programs in Listings A-1 and A-2 were used to transform this output to another form used for calculation of the similarity values. The final, transformed, data file is shown in Listing A-3.

LISTING A-1. SQRTBL.BAT

This program is an MS-DOS batch file that controls the conversion of SEDQUAL output from a sediment quality values comparison to a form used for the similarity value calculation. The 'strsubst' and 'splitfil' programs are proprietary products of PTI; the 'vp' program is Vedit Plus®, a commercial product.

APPENDIX B

Adjacent Station Pairs in Elliott Bay

APPENDIX B
Adjacent Station Pairs in Elliott Bay

The file listed below includes all stations in Elliott Bay that share a Thiessen polygon edge. The data were generated by constructing a TIN of all stations in ARC/INFO® and saving as a text file the names of the stations at the ends of every arc in the TIN.

LISTING B-1. SNTPDOS.FIL

The data columns in this file identify the data record (line) number, the arc identifier used by ARC/INFO®, the length of the arc connecting the stations (feet), and the survey and station identifiers of the two adjacent stations

Station Pairs for Elliott Bay

APPENDIX C

Computer Program to Calculate Similarity Indices

APPENDIX C
Computer Program to Calculate Similarity Indices

The program listed below was used to calculate values of the six similarity indices that were evaluated.

LISTING C-1. SIMILARI.MOD

```
MODULE Similarity;
(*================================================================

FILE:           SIMILARI.MOD
PROGRAM:    Similarity
PURPOSE:    Calculate measures of similarity between adjacent stations
            based on exceedances of P-2 sediment quality standards.

NOTES:          Originally created for PTI Contract No. C704-14-06.
            Meant to be used one time only.
            This program reads data from two free-format text files,
            each containing a single table of data with no missing entries.
            The files, and their contents, are:
            EBOVRP2.TXT
                Headers: none
                Columns: SURVEY STATION CHEM CONCENTRATION EXCEEDANCE FACTOR UNITS MEAS.BASIS
            SNTPDOS.FIL
                Headers: last line begins with "$"
                Columns: RECORD.NO ARC.NO ARC.LENGTH SURVEY1 STATION1 SURVEY2 STATION2

LIMITATIONS:    1) Input file names are coded into the program.
            2) This program was written for the JPI TopSpeed Modula-2
               compiler.

     X2Stat
This procedure calculates the X2 statistic, which is distributed
as Chi-square.  It reports only the sample statistic for two
stations, not the number of classes (chemicals in common) or the
degrees of freedom.  The number of classes is expected to be
independently known, and the degrees of freedom are equal to this
number (the number of deviations is 2N [where N is the number of
chemicals] and the expected value for each chemical is calculated
from the two station values, thereby losing a degree of freedom
for each pair of deviations.  No additional degrees of freedom are
lost because the chemicals are independent (the expected value for
one chemical is not affected by the values of other chemicals).
