Acknowledgements

This study would not have been possible without the support and contributions of others at the Washington State Department of Ecology (Ecology) and at the U.S. Geological Survey (USGS). We want to express our appreciation to the following:

USGS

- ◊ Michele Crouse for expediting public distribution of HYSEP and for her insights regarding use of the HYSEP program.
- ◊ The many hydrologists, technicians, and computer specialists who, over the years, built and maintained the stream gages and computer databases this study drew upon.

Ecology

- ◊ Will Kendra, Larry Goldstein, and Bill Backous who supported and funded this study.
- ◊ John Covert, John Roland, Linton Wildrick, Art Larson, Todd Kirk, Kirk Cook and Doug McChesney who reviewed and commented on drafts of this report.
- ◊ Joan LeTourneau who edited and formatted the final report.
- ◊ Steve Barrett for posting this report on the Internet.

Abstract

Automated hydrograph separation techniques were used to evaluate the groundwater contribution to total streamflow (baseflow) at active and inactive stream gaging stations throughout Washington State. Discharge records for 582 gaging stations, with at least three complete water years of daily mean streamflow data, were downloaded from the U.S. Geological Survey (USGS) National Water Information System. Station characteristics were compiled for each gage, including period of streamflow record, type and degree of regulation affecting the gage, watershed drainage area, USGS station number, station name, and gage location.

Summary statistics were calculated for annual mean streamflow and annual 7-day low flow for all 582 stations. Monthly, and in some cases annual, statistics for baseflow were then estimated using a USGS hydrograph separation software program called HYSEP (Sloto and Crouse, 1996) for those stations judged to be free of significant snowmelt or regulation effects.

Annual unit-area baseflow for the 294 stations free of significant regulation or snowmelt effects ranged from <1 to 11 ft³/sec/mi² with a median value of 2.9 ft³/sec/mi². Unit-area baseflow for stations located west of the Cascade Mountain crest averaged approximately 3.2 ft³/sec/mi². Stations located east of the crest averaged approximately 0.4 ft³/sec/mi². On average, groundwater discharge represented approximately 68% of total annual streamflow for the stations modeled. Estimated groundwater contributions to streamflow for the typical low flow months of July, August, September, and October averaged 86%, 86%, 77%, and 69% respectively. This suggests that reductions in groundwater discharge to streams during this period, due to increased groundwater withdrawals, may significantly impact the instream flows needed to sustain fish and maintain water quality. This highlights the importance of managing surface water and groundwater as a single interconnected resource.

The baseflow estimates provided in this report are best used as basin-scale averages. Any attempt to apply these values as absolute representations of groundwater inflow on either a basin scale or stream segment scale is inappropriate.

Study results were compiled in an ArcView® GIS project for spatial analysis, and a master database was assembled. A compact disc containing the tabular data and ArcView® project files generated during the study accompanies this report.

Glossary

Annual mean...[parameter] – the mean of the individual daily mean values for a parameter for one complete water year. For example, the “annual mean baseflow” for a given water year is the average of the 365 daily mean baseflow estimates which comprise the water year.

Annual 7-Day low flow – the lowest mean streamflow for 7 consecutive days in a water year. Also known as the annual 7-day minimum flow. This value should not be confused with the 7-day 10-year low flow statistic (7Q10), which represents the lowest mean discharge for 7 consecutive days that has a probability of occurring once in 10 years. Units typically presented in terms of cubic feet per second (ft^3/sec).

Baseflow – that component of streamflow derived from groundwater inflow or discharge. Baseflow can be represented by a variety of measurement units, including cubic feet per second (ft^3/sec) and inches (in). Baseflow presented in units of inches indicates the depth to which a stream’s drainage area would be covered if all of the baseflow for a given time period were uniformly distributed on it.

Cubic foot per second (ft^3/sec) – the rate of discharge representing a volume of 1 cubic foot passing a given point during 1 second. The value 1 ft^3/sec is equivalent to 7.48 gallons per second (gps), or 448.8 gallons per minute (gpm).

Daily mean streamflow – the mean value of stream discharge for a 24-hour period, derived from periodic measurements of stream stage. Units typically presented in terms of cubic feet per second (ft^3/sec).

Drainage area – the area, measured in a horizontal plane, which contributes surface runoff to a stream gage. For the purposes of this report, the contributing area for groundwater baseflow is assumed to be equal to the drainage area for surface runoff. Units typically presented in terms of square miles (mi^2).

Freshet – a sudden increase in stream discharge that results from the rapid melting of accumulated snow. In Washington the snowmelt freshet typically starts in March or April and continues until May, June, or July depending on the year and stream in question.

Hydrograph – a graphical plot of streamflow data over time.

Hydrograph separation – a procedure used to separate a streamflow hydrograph into baseflow and surface runoff components.

Interflow – the lateral movement of water in the unsaturated zone during and immediately after a precipitation event. The water moving as interflow discharges directly into a surface water body (Fetter, 1980).

Median annual...[parameter] – the median value of all the individual annual mean values estimated for a period of record. For example, if an annual mean baseflow value is estimated for a station with 12 years of data, the median annual baseflow value is the median of the 12 individual annual means. Only those years with no missing daily data are included in the median calculation.

Monthly mean...[parameter] – the mean of the individual monthly means for a specific month and period of record. For a station with 12 years of data, for example, the January monthly mean baseflow is the average of the individual monthly means for January of each year. Only those months with no missing daily data are included in the mean calculation for a particular month.

Return flow – water that enters the unsaturated zone, flows laterally down slope and then re-emerges at the foot of the slope. Return flow is distinguished from interflow because it does not discharge directly to a stream (Fetter, 1980).

Seepage study – a field survey conducted to quantify the interaction between groundwater and streams. Concurrent discharge measurements are made at points along the mainstem of a stream. The relative increase or decrease in discharge between measurement points that is not accounted for through physical diversion or tributary input is the volume of water exchanged between the stream and groundwater storage.

Surface runoff – the difference between total streamflow and estimated baseflow (total streamflow – estimated baseflow = surface runoff). Surface runoff is water that enters a stream relatively quickly after a storm event through processes other than baseflow discharge. The individual components of surface runoff (quickflow) can include overland flow, return flow, interflow, and direct precipitation on a stream.

Unit-area baseflow ($\text{ft}^3/\text{sec}/\text{mi}^2$) – a measure of baseflow normalized to drainage area. Derived by dividing the total baseflow discharge value for a basin by the square mileage area of the basin. For example, if the baseflow value for a drainage basin is estimated to be $44 \text{ ft}^3/\text{sec}$, and the total area of the drainage basin is 80 mi^2 , the unit-area baseflow for the basin is estimated to be $0.55 \text{ ft}^3/\text{sec}/\text{mi}^2$.

Water year – a term used to describe the 12-month period, starting on October 1 and ending on September 30. A water year is designated by the calendar year in which it ends. Thus, the year ending on September 30, 1997 is called the “1997 water year”

Introduction

Considerable effort has been expended to characterize the physical, chemical, and biological processes affecting Washington State's groundwater and surface water resources. However, comparatively little effort has gone toward understanding the complex interaction between groundwater and surface water, and the implications this interaction holds for environmental management and the formulation of water-use policy. Washington's increasing reliance on groundwater to supply new water uses, coupled with legal requirements to maintain instream flows and to protect water quality, necessitate a better understanding of surface water/groundwater relationships.

Nearly all streams interact with groundwater to some extent. Previous investigators have shown that groundwater discharge to streams (baseflow) commonly accounts for 50 percent or more of average annual streamflow, and can be a significant non-point source of chemical or nutrient input to streams (Winter et al., 1998). Depletion or contamination of an aquifer can have unforeseen consequences for hydraulically connected streams, leading, in turn, to streamflow depletion or contamination.

This study is intended as an early step toward improving our understanding of the baseflow characteristics of Washington rivers and streams. Such information is crucial for workers attempting to: 1) manage groundwater withdrawals, 2) prevent streamflow depletion, 3) quantify groundwater pollutant loading to streams and rivers, 4) define the role groundwater plays in maintaining streamflows, and 5) design and implement instream-habitat protection and restoration programs.

For this study, baseflow contributions to streams were estimated using a hydrograph separation software program called HYSEP (Sloto and Crouse, 1996). HYSEP is a public domain computer program developed and distributed by the U.S. Geological Survey (USGS). Hydrograph separation techniques divide a stream hydrograph into two major components: baseflow and surface runoff (Sloto and Crouse, 1996; Winter et al., 1998). Baseflow estimates derived through hydrograph separation have traditionally been considered a reasonable approximation of the volume of groundwater discharge to a stream (White and Sloto, 1990; Holtschlag and Nicholas, 1998; Rutledge and Mesko, 1996; Bachman, 1998).

Until recently, manual hydrograph separation was the most common method for estimating baseflow. However, manual techniques are time-consuming when applied to the long periods of record required to produce representative statistics. Automated analysis tools, such as the HYSEP program, have greatly enhanced our ability to perform these analyses. Baseflow estimates produced by the HYSEP program compare favorably with estimates obtained using manual hydrograph separation techniques (Sloto and Crouse, 1996).

Purpose and scope

The purpose of this study was to improve our understanding of the relative importance that groundwater discharge plays in maintaining streamflow in Washington State. To accomplish this goal, daily mean streamflow data for 582 USGS-managed stream gages throughout the state were compiled and evaluated. Hydrograph separation techniques were used to estimate monthly (and in some cases annual) baseflow statistics for 465 gaging stations judged to have appropriate data. Total annual streamflow and mean 7-day low flow statistics were calculated for all 582 stations, to aid future water-quality and instream-flow investigations.

This report does not eliminate the need for site specific baseflow investigations on either a stream or stream-reach basis. Rather it is intended to serve as a prioritization tool and starting point for such work. The baseflow values presented in this report provide basin-scale estimates of groundwater discharge to streams. Such estimates are useful for basin-to-basin comparisons of baseflow, for preparing initial water budget or recharge estimates for watersheds, and for developing preliminary estimates of groundwater pollutant loading to streams and rivers.

Previous investigations

Despite the importance of stream/aquifer interactions, published baseflow estimates are available for only a small subset of Washington's rivers and streams. Vaccaro et al. (1998) summarized baseflow estimates for a number of small drainage basins in the Puget Sound Lowland. These estimates were developed during recharge modeling studies (Deep Percolation Model-DPM), or were calculated by water-budget modeling (Hydrological Simulation Program-FORTRAN-HSPF).

Seepage surveys have been conducted by several investigators to quantify groundwater discharge to specific stream reaches (Covert et al., 1995; Larson and Marti, 1996; Erickson, 1993; Sinclair and Hirschey, 1992; Clark et al., 1999; Morgan and McFarland, 1996; and Turney et al., 1995). Mix (1977) and Woodward (1995) used hydrograph separation techniques to estimate baseflow contributions to the Colville River and several East King County watersheds, respectively.

No published studies were identified where automated hydrograph separation techniques have been applied to Washington streamflow data. However, use of computerized hydrograph analysis methods has increased over the last decade, as investigators face the need to characterize groundwater/surface water interactions throughout the nation. Regional-scale baseflow studies using hydrograph analysis were recently completed for:

- ◊ The Great Lakes area (Holschlag and Nicholas, 1998)
- ◊ Pennsylvania (White and Sloto, 1990)
- ◊ Tennessee (Hoos, 1990)
- ◊ The Chesapeake Bay area (Bachman, 1997; Langland et al., 1995)

- ◊ Appalachia Regional Aquifer System Analysis (Rutledge et al., 1996)
- ◊ The Central Savannah River Basin (Atkins et al., 1996)

Theoretical background

For streams and rivers that are little influenced by regulation or snowmelt effects, streamflow derives largely from the rapid runoff of precipitation following storm events (quickflow) and the slower, sustained discharge of groundwater (baseflow). These two streamflow components generally exhibit different signatures on a stream hydrograph. Quickflow manifests as rapid spikes or peaks on a hydrograph, while baseflow is comparatively smooth and sustained. This difference is the basis for computerized hydrograph separation techniques, which use an algorithm to draw a line between baseflow and quickflow, in turn allowing daily values for each component to be calculated.

The HYSEP program provides three methods for separating the surface runoff and baseflow components of streamflow. The method selected for this study, the “local minimum” method, generally provides the lowest baseflow estimates of the three approaches, and is therefore considered the most conservative of the models.

Separating streamflow into surface runoff and baseflow components is based on identifying when surface runoff ceases following a storm event and streamflow is entirely sustained by baseflow. The algorithm used by HYSEP to estimate the time duration of surface runoff from a storm event is based on the empirical relation:

$$N = A^{0.2} \quad (Eq. 1)$$

where (N) is the number of days after which direct surface runoff ceases, and (A) is the drainage area in square miles (Pettyjohn & Henning, 1979; Sloto & Crouse, 1996). Once the value of N is determined for a basin, a time interval $2N^*$ is estimated by determining the odd integer between 3 and 11 that is nearest $2N$ (e.g., if $N = 2.26$, interval $2N^* = 5$). The local minimum method checks each day of a period of record to determine if it has the lowest discharge in one half the interval minus 1 day [$0.5(2N^*-1)$ days] before and after each day being considered. If this criterion is satisfied, the discharge value for that day is considered a “local minimum” value, and is connected to other local minimum values. The baseflow discharge for all days between local minimums is estimated using linear interpolation. Figure 1 shows an example of the graphical output for a station modeled using the local minimum method.

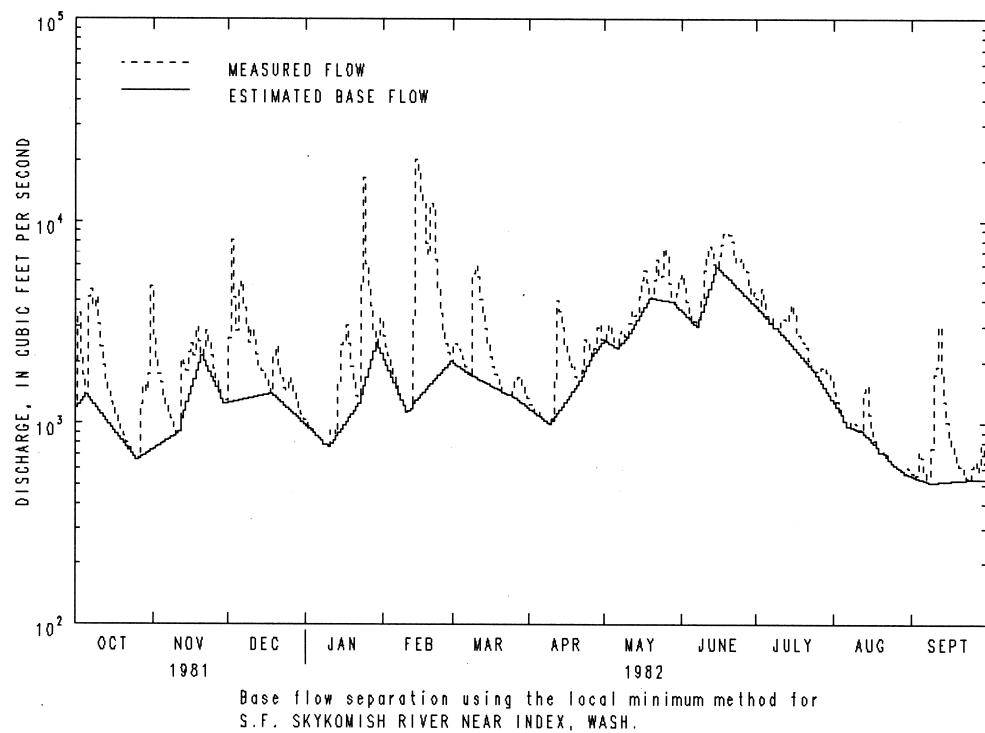

Figure 1. Base Flow Separation Using the Local Minimum Method, S.F. Skykomish River Near Index, WA. (USGS 12133000)

The 0.2 exponential constant used in Equation 1 is an empirically derived value. Applying a universal constant across all stream basins undoubtedly introduces some error into the baseflow estimates produced by HYSEP (Fetter, 1980). Defining the absolute error introduced by use of a generic constant requires detailed knowledge about the characteristics of each basin being evaluated and is beyond the scope of this project.

Computer algorithms, such as those used by HYSEP, are unable in many situations to account for external factors that can modify a stream hydrograph. Reservoir releases and snowmelt, for example, can mitigate the flashy signature of storm events, leading to over-estimation of baseflow (Fetter, 1980, Freeze and Cherry, 1979). The influences of these and other processes on the baseflow estimates produced by HYSEP are discussed in detail later in this report.

Study Methods

Compilation of streamflow data

Daily mean streamflow data for all active and discontinued stream gages within Washington State were downloaded in ASCII format from the USGS National Water Information System (NWIS) in Tacoma, WA. (Bartholoma, 1977). Two stations (USGS 12323000 and 12438700) are managed by the USGS but are located in Canada. One station, the Teanaway River below forks near Cle Elum (USGS 12480000), also includes streamflow data collected by the Bureau of Reclamation for 1974-1995.

Those stations with at least three complete years of discharge data (582 in all) were subsequently selected and prepared for further analysis (Plate 1). The raw NWIS data for these stations, (in ASCII WATSTORE format), was converted to binary WDM format using the USGS program IOWDM (Flynn et al., 1997). All 582 stations were analyzed to define mean annual discharge and mean 7-day low flow summary statistics for each station by water year.

Using descriptions provided by the USGS, stations were categorized based on the degree and type of regulation reported to effect each gage (Wiggins et al., 1996; State of Washington, 1955 and 1962). The categories include:

- High degree of stream regulation: reservoirs, diversions, or other factors significantly alter the stream discharge on an annual, seasonal, or daily basis.
- Moderate degree of stream regulation: reservoirs, diversions, or other factors have a moderate effect on the stream's annual, seasonal, or daily discharge.
- Low degree of stream regulation: reservoirs, diversions, or other factors have only a slight effect on the stream's annual, seasonal, or daily discharge.
- Non-regulated streams: no reservoirs, significant diversions, or other factors are reported to effect the stream discharge.

On the basis of this information, 117 stations were judged to be moderately to highly influenced by streamflow regulation due to reservoir releases, hydropower generation, interbasin transfers of water, or flood control activities. Due to the likelihood that the stream hydrograph for these stations had been significantly altered by regulation, these stations were excluded from further baseflow analysis. An additional 171 stations were judged to be influenced by seasonal snowmelt effects and were excluded from baseflow analysis for those months when snowmelt significantly effects streamflow. Annual baseflow statistics were not calculated for these stations.

A total of 14,704 water years of data were evaluated during this study. The length of data record used for analysis ranged from 3 to 106 water years. The average length of data record was 25 water years. Sixty-five percent (382) of the stations had little or no reported streamflow regulation above the gage. The remaining stations were subject to moderate or high levels of regulation. Approximately 30% (173) of the stations were active stream gaging sites as of 1997. The remainder of the stations are inactive.

Statistical data analysis

Using the algorithms described above, the HYSEP program analyzes the entire streamflow data set for a station, and produces baseflow and surface runoff estimates for each day having valid input data. These daily estimates are then used to produce, where appropriate, monthly and annual summary statistics in a variety of measurement units.

HYSEP calculates mean monthly baseflow statistics for each water year by averaging the daily baseflow estimates for each month within the year. These values are referred to as “monthly means”. Monthly statistics are generated only for those months that do not have missing daily values. The monthly statistics were collectively analyzed to determine the minimum, maximum, and median monthly mean baseflow and streamflow statistics (by month) for the period of record.

HYSEP also calculates the “annual mean” baseflow for every complete¹ water year in a period of record. Annual values are derived by averaging the daily baseflow estimates for each water year. The annual means estimated by HYSEP for all the years in a period of record were then collectively analyzed to determine the minimum, maximum, and median annual mean baseflow values for each station. Figure 2 graphically illustrates the summary statistics developed for annual baseflow. A similar analysis was conducted for all stations for total streamflow.

Daily mean streamflows were also analyzed for each station to calculate the annual 7-day low flow for each year. These statistics were calculated using SWSTAT, a public domain software program distributed by the USGS (Flynn et al., 1995). The annual 7-day low flow values for each station were then collectively analyzed to determine the minimum, maximum, and median 7-day low flow for the period of record.

Reported streamflow and baseflow values have been rounded to conform to standard USGS protocol (Wiggins, 1996). Discharges are reported to the nearest hundredth for values less than 1 cubic foot per second (ft^3/sec), to the nearest tenth from 1 to 9.99 ft^3/sec , and the nearest unit from 10 to 999 ft^3/sec . All values of 1,000 ft^3/sec or greater are rounded to three significant digits.

¹ The HYSEP program will not calculate an annual mean for years with missing daily data.

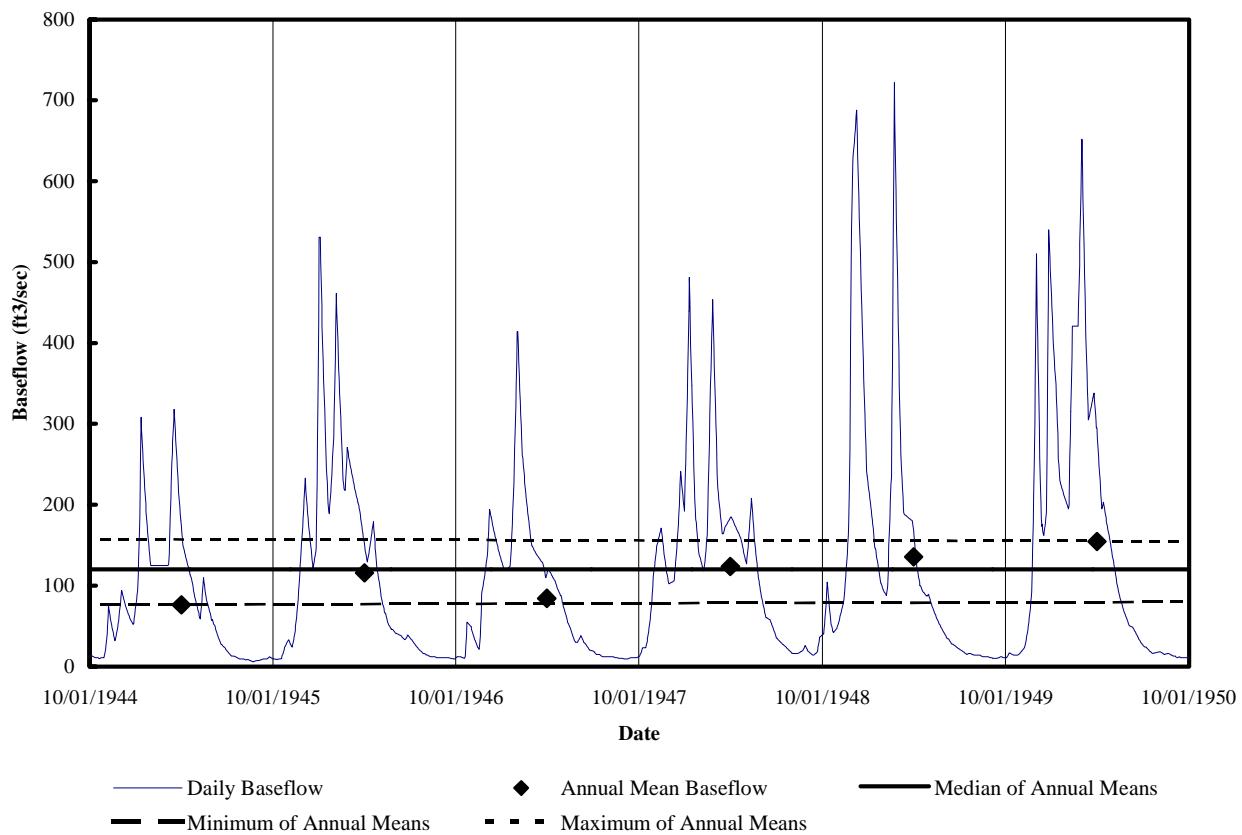

Figure 2. Graphical Depiction of Baseflow Statistics, Black River at Littlerock, WA. (USGS 12029000)

Compilation and preparation of digital data

Tabular data

Data developed during this study were compiled as ASCII tab-delimited data files and are contained on the accompanying compact disc (Appendix D). The files include:

- a station descriptor table
- a regulation descriptor table
- a table of annual baseflows and streamflows by station and water year
- a table of minimum, maximum, and median annual baseflow/streamflow summary statistics by station
- a table of monthly baseflow/streamflow summary statistics by station

A directory and instructions for viewing these files are included in the README.txt file found on the compact disc.

Geographic data

As part of this project an ARCINFO® point coverage was developed based upon the USGS reported latitude/longitude coordinate pairs for each gaging station². ArcView® GIS software was used to spatially map and evaluate the annual and monthly baseflow statistics derived from the HYSEP program output. A compiled ArcView® project file with associated data tables and graphical summaries of the annual and monthly HYSEP output can be found on the digital compact disc that accompanies this report (Appendix D). ArcView® (used to prepare the plates accompanying this report) allows users to rapidly access statistical information for an individual site, or to spatially analyze areal trends in baseflow or streamflow characteristics for multiple stations.

Line graphs of estimated annual baseflow, total streamflow, and 7-day low flow versus water year were prepared for all stations with at least 10 years of data, an example of which is shown in Figure 3. Similarly, graphs of estimated baseflow, total streamflow, and surface runoff versus month were prepared for all stations with at least three years of data, an example of which is shown in Figure 4. Both graph types are hot-linked³ to the ArcView® project file. The average monthly values were determined using only those months that had no missing daily values. Thus the total number of months (N) used to define the mean for individual months may vary.

Specific operating instructions, a file directory, and attribute field definitions for the ArcView® project file are presented in the README.txt file found on the compact disc.

² The coordinates for Stations 12033000, 12419500, and 12433200 were corrected to address known locational errors.

³ “hot-linked” graphics are files that are automatically opened within ArcView® by double-clicking on a point of interest within the GIS environment.

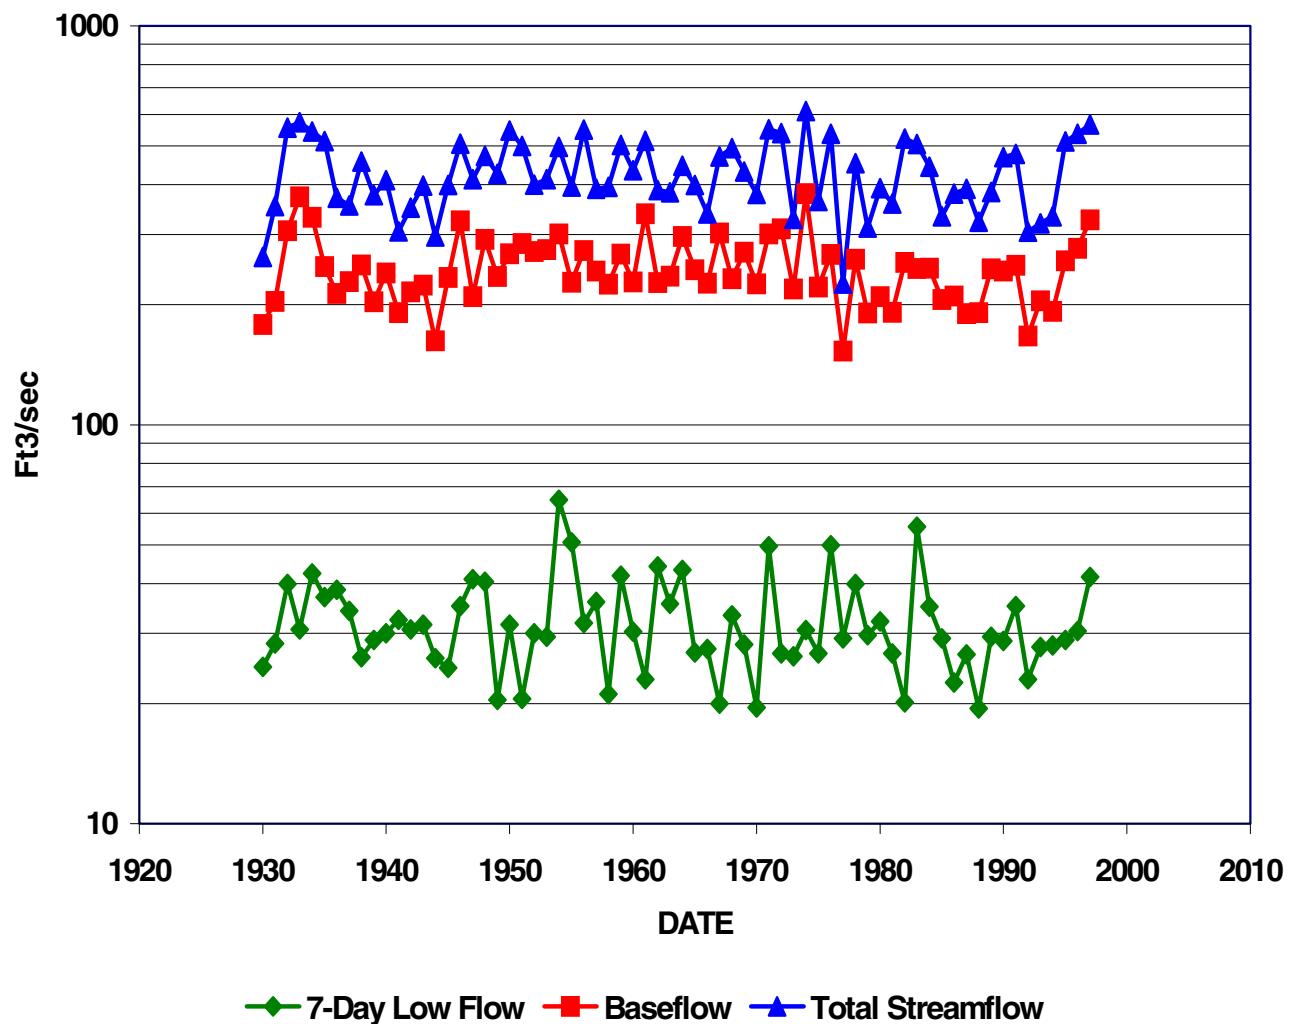

Figure 3. Comparison of Annual Mean Streamflow, Estimated Annual Mean Baseflow, and Annual 7-Day Low Flow, Naselle River Near Naselle, WA. (USGS 12010000)

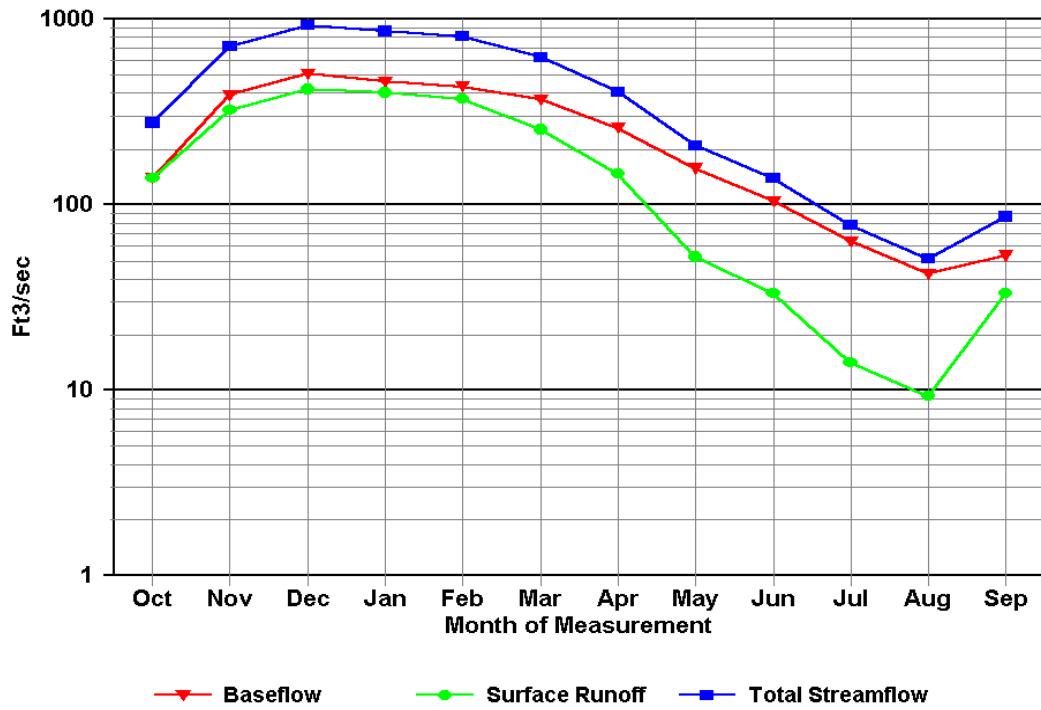

Figure 4. Comparison of Estimated Monthly Mean Baseflow, Mean Surface Runoff, and Mean Streamflow, Naselle River Near Naselle, WA. (USGS 12010000)

Results

Plate 1 shows the location, name, USGS Site ID, and map ID of the gaging stations evaluated during this study. A master table describing significant characteristics of each station is presented in Appendix A. Included are the length and period of record analyzed; drainage area; estimated degree, type, and timing of streamflow regulation; and station location information. The years of data used for analysis, the degree of regulation, and the drainage area size for each station are presented in map form on Plate 2 (Plates 2A, 2B, and 2C).

Monthly statistics

Appendix B contains summary monthly statistics for estimated baseflow, surface runoff, and total streamflow, ordered sequentially by station number. Monthly mean baseflow as a percentage of total streamflow is presented in map form on Plate 3 for February, May, August, and November (Plates 3A, 3B, 3C, and 3D respectively). Baseflow estimates are not included on Plate 3 for stations that are known to be significantly influenced by regulation or snow melt.

The monthly mean baseflow contribution to total streamflow for the critical low-flow months of July, August, September, and October averaged 86% (n=360), 86% (n=459), 77% (n=461), and 69% (n=463), respectively.

Annual statistics

Appendix C contains summary annual statistics for estimated baseflow, total streamflow, and 7-day low flow ordered by station number. The median of the annual means for total streamflow, 7-day low flow, and baseflow are presented for all applicable stations on Plate 4 (Plates 4A, 4B, and 4C, respectively). Estimated median annual mean baseflow as a percent of total streamflow is presented in Plate 5A for all applicable stations. Estimated median annual mean baseflow (in inches) and median annual mean unit-area baseflow (in $\text{ft}^3/\text{sec}/\text{mi}^2$) is presented in Plates 5B and 5C respectively. Baseflow estimates are not included on Plates 4 and 5 for those stations that are known to be significantly influenced by regulation or snow melt.

The median annual mean baseflow contribution averaged 68 percent for the 294 stations with sufficient data to perform the analysis and ranged from 29 -100 percent of total streamflow. The median annual baseflow contribution for these stations averaged 40 inches and ranged from 0 to 153 inches. Median annual unit-area baseflow averaged $2.9 \text{ ft}^3/\text{sec}/\text{mi}^2$ and ranged from <1 to $11 \text{ ft}^3/\text{sec}/\text{mi}^2$. The average median annual unit-area baseflow for 263 stations west of the Cascade crest ($3.2 \text{ ft}^3/\text{sec}/\text{mi}^2$) was significantly greater than that for 33 stations lying east of the crest ($0.4 \text{ ft}^3/\text{sec}/\text{mi}^2$).

Data Limitations

While the HYSEP program avoids the inconsistencies and biases inherent in manual methods, hydrograph separation remains an empirical technique that simplistically divides the complex processes sustaining surface water drainage within a watershed. Despite this limitation, the consistent application of baseflow separation algorithms to multiple drainage basins allows regional comparisons of the role groundwater plays in sustaining streamflow.

A variety of factors can influence the accuracy of baseflow estimates derived via hydrograph separation, including: the period and length of data record, the degree and timing of streamflow regulation, snowmelt effects, climatological influences, bank storage effects, and the reliability of the source data. While an effort has been made in this report to screen out stations where these effects are judged to introduce an unacceptable error, the data user should learn to recognize potential sources of error in the baseflow estimates. Some of these factors are discussed below.

Period of data record

Less than 30 percent of the gaging stations analyzed for this study are presently monitored. This suggests that the baseflow and streamflow estimates provided in this report may not accurately depict current conditions for many streams, particularly those where watersheds are undergoing rapid land use changes such as urbanization or intensive logging. The estimates provided in this report are only applicable to the period of record analyzed.

Length of data record

Long periods of data record are typically less influenced by short-term climatic variability than are short periods of record, and thus tend to produce more representative estimates of “average” baseflow or streamflow conditions. Figure 3 shows the annual data for the Naselle River near Naselle (USGS 12010000) for water year 1930 to present. Based on 68 years of data, the average annual 7-day low flow and estimated baseflow for this station were 32 and 246 ft³/sec respectively. However, evaluating this data using a moving 10-year period of record yielded 7-day low flow values ranging from 27 to 38 ft³/sec, while estimated baseflows ranged from 210 to 273 ft³/sec. This example demonstrates the importance of considering the length of data record, and climatological conditions during the record period, when judging the baseflow values.

Streamflow regulation

Stream regulation for flood control, irrigation, hydropower, and other purposes can significantly alter the timing and magnitude of streamflow within a watershed. Previous authors have shown that the effects of stream regulation on baseflow are highly variable

and site specific. In some cases, an apparent increase in baseflow was noted after regulation was initiated, in others an apparent decrease (White and Sloto, 1990). Defining how regulation has altered the timing and/or volume of streamflow at a gaging station is the key to interpreting how regulation might have affected estimated baseflow. For example, reservoir storage of winter runoff may mitigate the flashy runoff processes normally observed in a non-regulated stream. The subsequent release of stored surface runoff, if it occurs gradually, can mimic baseflow on a hydrograph. Under such circumstances HYSEP may incorrectly interpret the gradual release of stored surface runoff as baseflow.

An example of regulation effects is shown for the Wynoochee River above Black Creek near Montesano (USGS 12037400) (Figure 5).

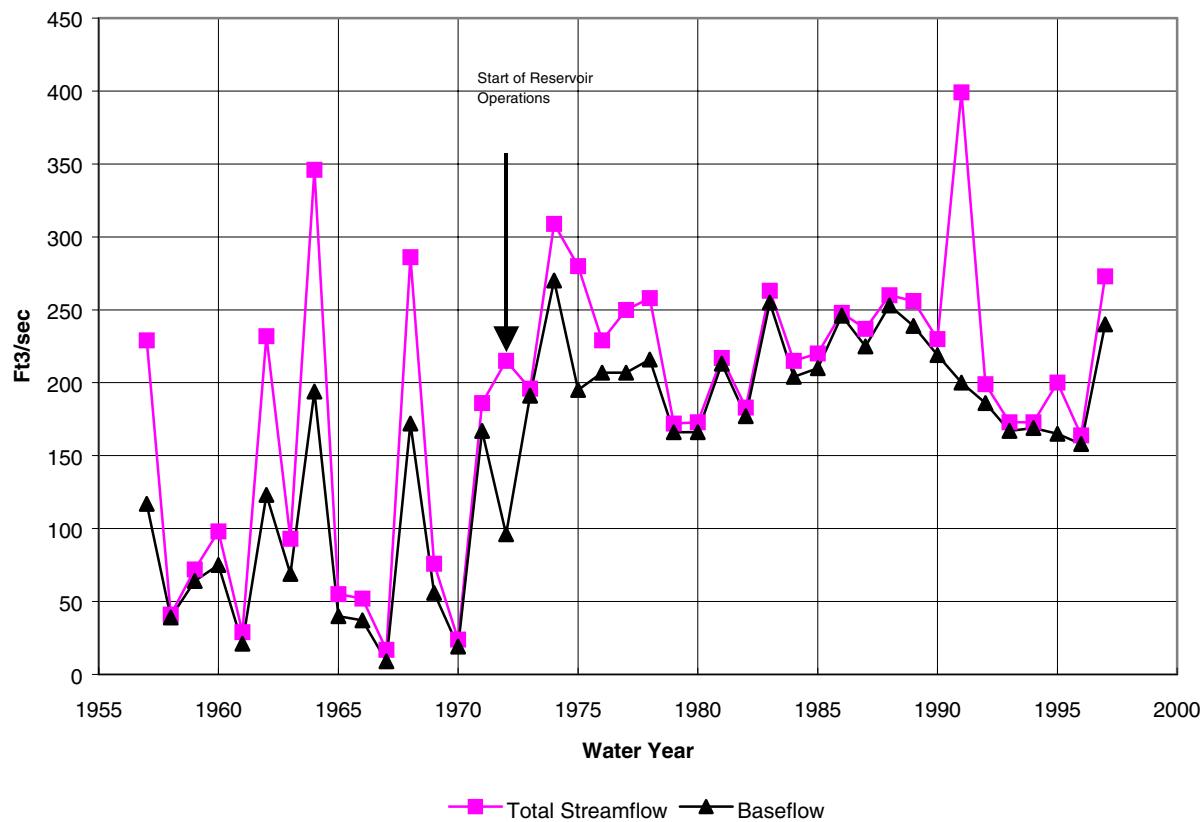

Figure 5. August Baseflow and Total Streamflow, Wynoochee River Above Black Creek Near Montesano, WA. (USGS 12037400)

The plot of mean August baseflow and total streamflow exhibits significantly different characteristics for the pre- vs. post-regulation periods. Streamflow and baseflow values for the pre-regulation period (1957-1971) averaged 122 and 80 ft³/sec respectively, while post-regulation streamflow and baseflow (1972-1997) averaged 230 and 202 ft³/sec respectively. Prior to regulation baseflow comprised 65% of total August streamflow. This value rose to 87% following the onset of regulation, an apparent increase of 22%. In this example regulation significantly altered the seasonal streamflow distribution, resulting in erroneous post-regulation baseflow estimates for August.

It is important to note that the onset of regulation has comparatively little effect, in this case, on the *annual* baseflow estimates for this station. Figure 6 reveals very little difference in estimated annual baseflow and total streamflow following the onset of reservoir operations, although annual mean 7-day low flow values increase dramatically. This highlights the importance of examining both the annual and seasonal baseflow data for a station. HYSEP's inability to distinguish between regulated and non-regulated streamflow can lead to false conclusions regarding both the annual and monthly baseflow characteristics of a watershed.

To assist readers, we have compiled relevant station information such as the number of years of data modeled, the period of data record, and reported regulation information for each station (Appendix A). As an additional precaution, we have chosen not to produce baseflow statistics for stations that are known to be moderately or highly influenced by reservoir storage and/or releases. The degree, type, and timing of regulation effects, if any, should be carefully considered when evaluating data for the remaining stations.

Drainage area

Several authors have recommended against the use of hydrograph-separation techniques to derive baseflow for watersheds exceeding 400 to 500 square miles in size (White and Sloto, 1990; Holtschlag and Nicholas, 1998; Rutledge and Mesko, 1996). This is due to concerns that storm events or watershed hydrogeologic characteristics are likely to be non-uniform over larger areas. Only 39 (~ 8 percent) of the stations evaluated for baseflow during this study have drainage areas greater than 500 mi². Users should employ caution when evaluating the results for these watersheds.

It should also be noted that the baseflow estimates produced by HYSEP are developed on the assumption that the groundwater basin contributing baseflow to a gaged stream coincides with the gaged surface water basin. For some watersheds this may not be the case. Stations with unusually high unit-area baseflow estimates may have significant groundwater contributions from outside of the surface water basin. Baseflows reported in inches and as unit-area values, in this report, should be considered approximations.

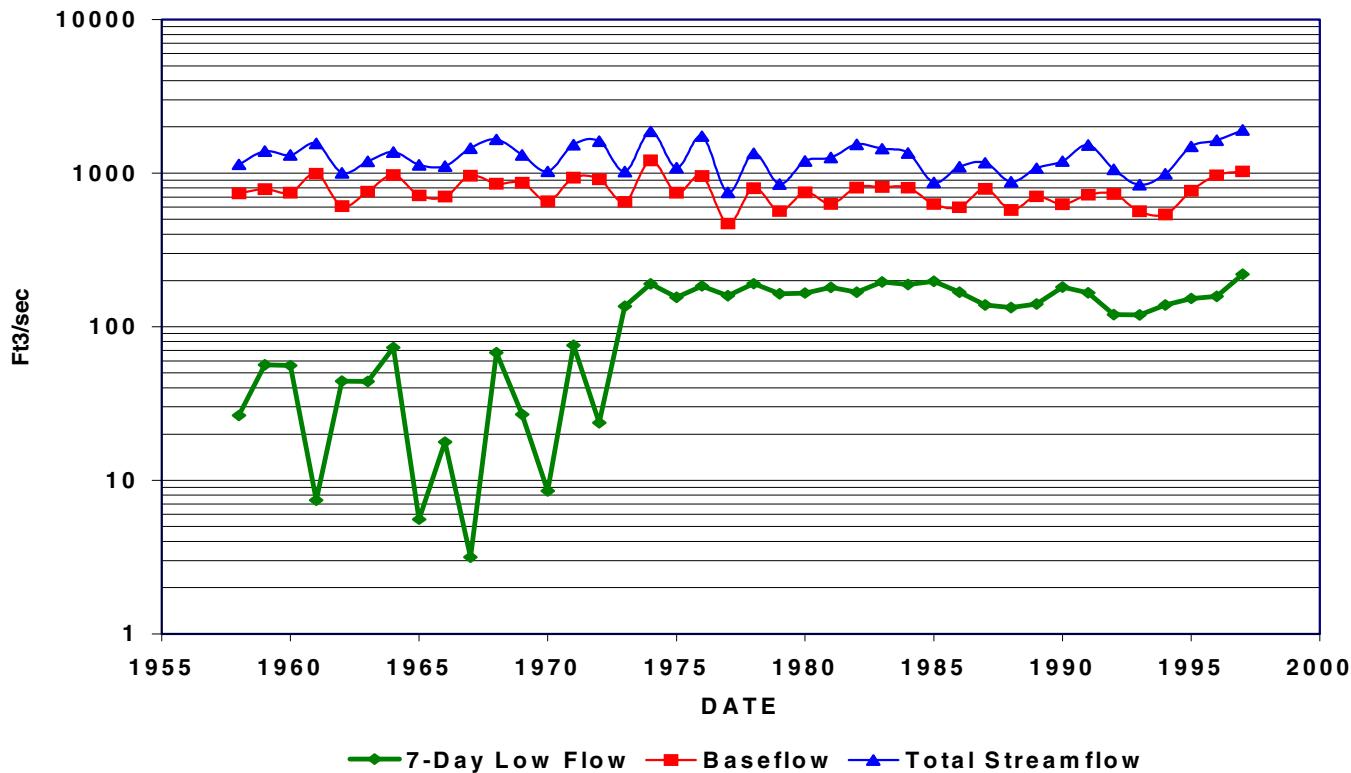

Figure 6. Comparison of Annual Mean Streamflow, Estimated Annual Mean Baseflow, and Annual 7-Day Low Flow, Wynoochee River Above Black Creek Near Montesano, WA. (USGS 12037400)

Snow/glacial melt

Meltwater is another significant factor that potentially affects the accuracy of baseflow estimates. Many streams in Washington (particularly Eastern Washington) derive a significant percentage of their annual discharge from melting snow and/or glacial meltwater (snowmelt). Snowmelt (like reservoir releases) can mimic groundwater discharge on the hydrograph, making it impossible for HYSEP to differentiate between the two processes. Where this happens, HYSEP aggregates snowmelt and groundwater discharge, and therefore produces erroneously high baseflow estimates.

Figure 7 is a plot of monthly baseflow, surface runoff, and total streamflow for Chamokane Creek (USGS 12433200) for the station period of record. This graph illustrates the typical pattern for snowmelt influenced streams, i.e., a gradual but significant increase in total streamflow during the spring snowmelt period. Because it is unable to differentiate between snowmelt and groundwater discharge, HYSEP incorrectly predicts that groundwater discharge to the creek accounts for approximately 80-85% of

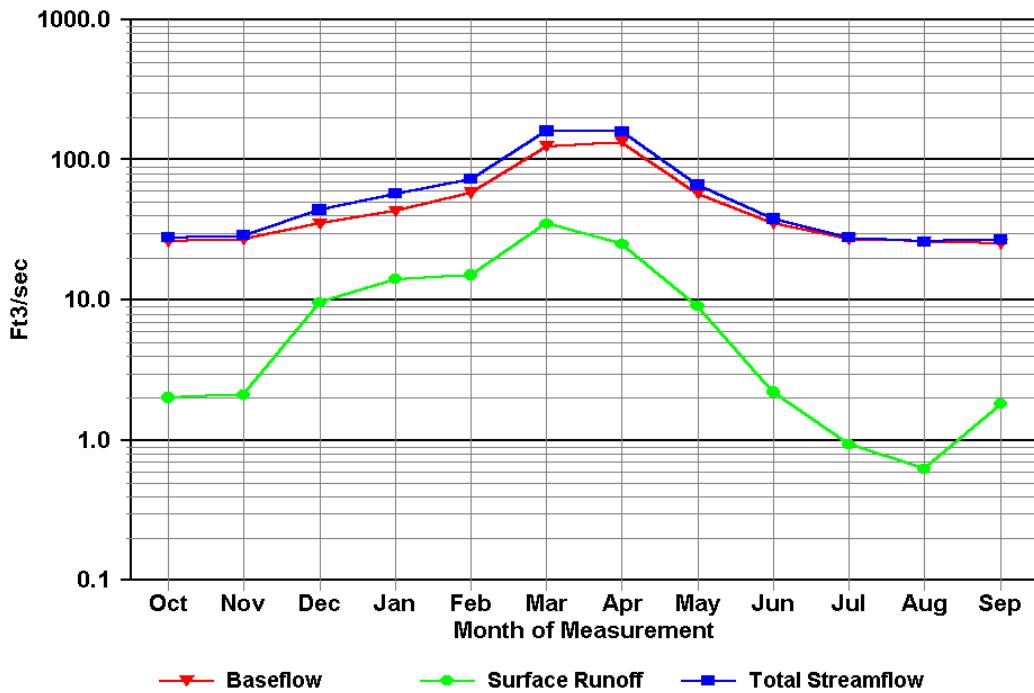

Figure 7. Comparison of Estimated Monthly Mean Baseflow, Mean Surface Runoff, and Mean Streamflow, Chamokane Creek Below Falls Near Long Lake, WA (USGS 12433200)

total discharge during the March–May period. In reality a significant proportion of the flow during this period (and on an annual basis) is derived from snowmelt (Covert, 1999). During the remainder of the year, when snowmelt is not a significant factor, HYSEP correctly predicts groundwater contributions to total streamflow. In this case, HYSEP would incorrectly predict that Chamokane Creek is, on an annual basis, a groundwater driven system, when in fact it is dominated by surface runoff processes.

Given HYSEP’s inability to differentiate between snowmelt processes and groundwater discharge, no annual baseflow estimates are presented for those stations that have obvious and significant snowmelt influences. In addition, we did not produce monthly baseflow statistics for these stations for the period of highest snowmelt (March/April – June/July).

Alternative baseflow analysis techniques

The baseflow estimates developed through hydrograph separation are not always directly correlative to those derived through other analysis methods such as seepage studies, HSPF modeling, or Darcy-flux calculations. Hydrograph-separation techniques define average baseflow characteristics for an entire gaged watershed based on long-term streamflow data. An assumption of hydrograph-separation methods is that groundwater contribution to streamflow is equally distributed throughout the length of the gaged stream. This is rarely the case.

In contrast, stream-seepage studies typically provide a “snapshot” perspective of groundwater discharge, based on the stream conditions prevailing at the time of the study. A significant advantage of field seepage studies is that one can identify both losing and gaining stream reaches. The reach specific baseflow values obtained through seepage studies may differ, by an order of magnitude or more, from the basin-average values presented in this report.

Summary and Conclusions

This study was undertaken to improve our understanding of the hydrologic interactions between groundwater and surface water within Washington State. Increasing reliance on groundwater to meet the growing demand for fresh water, coupled with legal requirements to maintain streamflows and to protect water quality, necessitates a better understanding of the surface water/groundwater connection.

Five hundred and eighty-two active or discontinued USGS stream gaging stations with at least three complete years of discharge data were initially examined for the analysis. The stations had an average of 25 years of data and ranged from a low of three years to a high of 106 years. Twenty percent (117) of the stations evaluated are highly to moderately affected by streamflow regulation due to reservoir releases, hydropower generation, interbasin transfers of water, or flood control activities. The remaining streams have little to no reported regulation above the station.

Summary statistics were calculated for total annual streamflow and annual 7-day low flow for all 582 stations. After screening to identify stations judged to be significantly influenced by regulation, computerized hydrograph-separation techniques were used to define the groundwater component of streamflow (baseflow) for 465 stations with little-to-no reported regulation. Summary statistics for monthly and annual baseflow estimates were then calculated for all stations with appropriate data.

For the 294 stations evaluated for annual baseflow, estimated median annual unit-area baseflow ranged from less than 1 to approximately $11 \text{ ft}^3/\text{sec}/\text{mi}^2$, and averaged $2.9 \text{ ft}^3/\text{sec}/\text{mi}^2$. Unit-area baseflow for 263 stations located west of the Cascade Mountain crest averaged approximately $3.2 \text{ ft}^3/\text{sec}/\text{mi}^2$. For the 33 stations located east of the crest, unit-area baseflow averaged approximately $0.4 \text{ ft}^3/\text{sec}/\text{mi}^2$. Estimated median annual baseflow, as a percentage of total streamflow, averaged 68%, and ranged from 29 to 100 percent.

Estimated baseflow contributions (mean monthly) to total streamflow for the critical low-flow months of July, August, September, and October averaged 86%, 86%, 77%, and 69%, respectively. The dominance of streamflow by groundwater discharge during these months, when water use is typically highest and streamflows are low, highlights the importance of managing surface water and groundwater as a single interconnected resource. With increased reliance on groundwater to supply new development, the likelihood of reducing the natural discharge of groundwater to streams increases. Failure to acknowledge and account for this connection during future groundwater allocation and land-use permitting decisions may adversely affect senior surface water rights, surface water quality, and the instream flows needed to sustain fish and other aquatic organisms.

The baseflow estimates provided in this report are best used as basin-scale averages. Any attempt to apply these values as absolute representations of groundwater inflow on either a basin scale or stream segment scale is inappropriate. Hydrograph separation is a

comparatively simplistic tool that may provide erroneous results for streams and rivers influenced by significant regulation or snowmelt. Readers of this report are responsible for judging the validity of the estimates provided, based on the unique characteristics of the drainage basin in question and the intended use of the information.

Recommendations and Suggestions for Additional Study

We recommend that inactive gages be re-established in rapidly developing watersheds, especially those where groundwater contributes significantly to streamflow. This will help define current baseflow conditions and trends.

We suggest the following as possible future areas of investigation.

1. Use baseflow data to estimate groundwater recharge

Estimating the annual volume of groundwater recharge within a watershed is a critical aspect of many hydrogeologic investigations. This is particularly true for studies involving the calibration of numerical groundwater-flow models or preparation of water budgets. For watersheds in hydraulic equilibrium, baseflow can be used to derive basin average estimates of recharge (Hoos, 1990; Mau and Winter, 1997; Rutledge and Daniel, 1994; Rutledge and Mesko, 1996). The baseflow estimates provided in this report could be used to estimate the mean annual volume of groundwater recharge for the drainage area lying above each of the modeled gages.

2. Evaluate groundwater solute loading to streams and rivers

By integrating baseflow estimates with groundwater-quality information, it is possible to estimate groundwater solute loading to streams and rivers (Bachman, 1997; Bachman et al., 1998; Langland et al., 1995). Water-quality data can be linked via GIS software to well sites within a modeled watershed to define the concentration and spatial distribution of solutes of concern. Baseflow estimates can then be integrated with this information to estimate loading.

3. Evaluate the effects of land-use changes on streamflow

Logging operations, urbanization, and other land-use changes can significantly alter the seasonal and annual distribution of streamflow within a watershed (Dunne and Leopold, 1978). It is likely that such changes can also affect the seasonal and annual distribution of baseflow. The information presented in this report could be used in conjunction with land-use and water-use data to help define the effects of urbanization, forestry practices, and other land uses on groundwater discharge to streams. Understanding how these activities have influenced streamflows may enable planners to formulate policies to minimize the undesirable effects of future land-use changes.

Integral to this type of study is a proper trend analysis of the baseflow data presented in this report. Such studies may be particularly fruitful where peak flow and 7-day low flow data are also available for evaluation.

4. Estimate average water table hydraulic characteristics by watershed

Evaluating the hydraulic properties of aquifers is a fundamental aspect of most groundwater investigations. Such information is necessary for the proper design and calibration of groundwater-flow models, predicting the effects of groundwater withdrawals on streamflows and other wells, and understanding patterns of groundwater movement.

A number of authors have used baseflow information to estimate the hydraulic characteristics of shallow aquifer systems (Rutledge and Mesko, 1996; Bevans, 1986; Hoos, 1990; Trainer and Watkins, 1974). The baseflow estimates provided in this report could be used in similar fashion to develop preliminary estimates of hydraulic properties for water-table aquifers within Washington.

5. Define baseflow characteristics for ungaged watersheds

Despite the relatively large number of gaging stations evaluated during this investigation, large areas of the state have yet to be characterized. The lack of streamflow monitoring for most rivers and streams makes it impossible to define baseflow through hydrograph separation techniques. Regression analysis of basin characteristics (e.g., surficial geology, precipitation) for modeled vs. unmodeled watersheds may be a relatively efficient mechanism for estimating baseflow in ungaged watersheds.

* "Present" refers to stations active through water year 1997.

(1) The number of years of data evaluated for baseflow analysis. See the annual data table in Appendix-D to identify specific years evaluated for baseflow.

(2) An indication of the relative degree of streamflow regulation. See p. 5 of this report for an explanation of the ranking system.

(3) Type of

Regulation Description of Regulation

- D Flow effected by domestic, municipal, or industrial water diversions
- I Flow effected by irrigation withdrawals
- R Flow effected by reservoir releases. The initial date of regulation is indicated if known. For multiple reservoir systems, the indicated date is for the first reservoir constructed.
- N Flow effected by natural regulation such as lake storage, snowmelt, or other effects
- F Flow effected by reservoir retention and release for flood control
- S Stream flow supplemented by well discharge, interbasin transfer, or industrial/municipal discharges
- H Flow effected by hydropower diversion/generation
- A Flow effected by diversions for aquaculture/fish hatchery operations
- L Lowflows supplemented by reservoir releases
- U Natural flow effected by urbanization
- O Flow known to be effected by nonspecific causes (small impoundments, check dams, ground water pumping, etc)
- M Flow seasonally affected by significant snow melt or glacial-meltwater
